(57) **ABSTRACT**

A method for reducing a network addressing header is executable by a network communication device. Upon receiving a network packet, a first address in an IPv4 header of the packet is converted to a mapping index. A least significant segment of an address field of an IPv6 header of the packet is generated based on the mapping index, and the IPv6 header is utilized to encapsulate the packet. The IPv4 header is recoverable via the least significant segment of the IPv6 header, so that the IPv4 header may be optionally omitted in transmission of the packet.

# NETWORK COMMUNICATION SYSTEM, DEVICE, AND METHOD FOR REDUCING A NETWORK ADDRESSING HEADER

## BACKGROUND

### 1. Technical Field

Embodiments of the present disclosure relate to electronic network communication systems and devices, and to a method for reducing a network addressing header.

### 2. Description of Related Art

Internet protocol version 4 (IPv4) has long been used as the Internet addressing standard. The number of IPv4 addresses, while vast, is finite, and address exhaustion is an emerging problem. Internet protocol version 6 (IPv6) was developed to solve address depletion associated with IPv4-based Internet use, and has features such as an expanded 128-bit address system, a simplified header structure, improved quality of service (QoS), and enhanced security.

However, long packet addressing headers degrade the processing speed of routers and nodes that process Internet traffic, thereby slowing down the overall performance of the Internet. In particular, multimedia traffic, such as voice over Internet protocol (VoIP) traffic or video conference traffic, is significantly affected by transmission delay or jitter of the network.

In reality, the current Internet cannot be rapidly converted into an IPv6 network since the IPv4 network is widely used. The IPv4 network and the IPv6 network will coexist for the time being while the IPv4 network is gradually replaced by the IPv6 network.

Coexistence of IPv6 hosts/routers and IPv4 hosts/routers in an IPv4/IPv6 combination network induce coexistence of IPv4 and IPv6 addressing headers during packet transmission, such as in an IPv4 over IPv6 context or an IPv6 over IPv4 context. Coexistence of IPv4 and IPv6 addressing headers slows down addressing header processing.

## BRIEF DESCRIPTION OF THE DRAWINGS

FIG. 1 is a block diagram of one embodiment of an electronic network communication device for reducing a network addressing header, in accordance with the present disclosure;

FIG. 2 is a schematic diagram of one embodiment of a network system for reducing a network addressing header, in accordance with the present disclosure;

FIG. 3 is a flowchart of one embodiment of a method for reducing a network addressing header, in accordance with the present disclosure;

FIG. 4 is a schematic view of a packet with an IPv4 addressing header utilized to generate a mapping index and a counter index, in accordance with the present disclosure;

FIG. 5 is a schematic view of a packet with an IPv6 addressing header that includes two interface identifications, each of which is constituted by the mapping index of FIG. 4, in accordance with the present disclosure;

FIG. 6 is a flowchart of one embodiment of a method for restoring an IPv4 addressing header, in accordance with the present disclosure;

FIG. 7 is a schematic view of a packet with an IPv4 addressing header utilized to generate a corresponding modified packet with an IPv6 addressing header, in accordance with the present disclosure; and

FIG. 8 is a schematic view of the modified packet of FIG. 7 utilized to generate a corresponding further modified packet with a restored IPv4 addressing header, in accordance with the present disclosure.

## DETAILED DESCRIPTION

The disclosure is illustrated by way of example and not by way of limitation in the accompanying drawings, in which like reference numerals indicate similar elements. Various embodiments illustrate different features of the disclosure. It should be noted that references to “an” or “one” embodiment in this disclosure are not necessarily to the same embodiment, and such references can mean “at least one.” The descriptions of components in the embodiments are given for the purpose of illustrating rather than limiting.

Embodiments of a network communication system and device, and a method for reducing a network addressing header, are detailed in the following description.

The disclosed network communication systems and network communication devices for reducing a network addressing header may be implemented as stand-alone systems or devices, or may be integrated into various network gateway devices or network terminal devices. The various network gateway devices comprise bridges, routers, switches, hot spots, and access points for wireless networking. The various network terminal devices comprise set-top boxes, cell phones, tablet personal computers, laptop computers, multimedia players, digital cameras, personal digital assistants (PDAs), navigation devices, and mobile internet devices (MIDs).

With reference to FIG. 1, a processor **151** serves as a central processing unit (CPU) of a network communication device **100**, and may comprise various integrated circuits (ICs) operable to process data and execute machine-readable instructions. The connections between the components of the network communication device **100** may comprise serial or parallel connections of wired or wireless communication.

A communication unit **156** establishes wired or wireless communication channels through which the network communication device **100** connects to and performs communication with remote and local servers, such as packetized data communication. For example, the communication unit **156** connects to a remote server (not shown) through a port **102** and a wide area network, and connects to a local server (not shown) through a port **101** and a local area network.

For example, the communication unit **156** establishes a wired network communication channel to the Internet or the remote server. The communication unit **156** comprises software and hardware components utilized for the wired network communication channel. The software components comprise computerized programs or instructions, while the hardware components comprise electronic circuits, ICs, and physical ports and connectors.

For example, the communication unit **156** establishes a wireless communication channel through which a portable device (not shown), such as a network terminal device, may connect to and exchange data with the network communication device **100**. The communication unit **156** establishes a wireless communication channel to the Internet or a server in the Internet. The communication unit **156** comprises antennas, and base band and radio frequency (RF) chipsets, all of which are for infrared communication, wireless local area network communication, and/or cellular communication, such as wideband code division multiple access (W-CDMA) and high speed downlink packet access (HSDPA). Through the established wireless communication channels, the network communication device **100** serves as a wireless LAN access point through which the portable device connects to the Internet.

The processor **151** may be packaged as one chip, or comprise a plurality of chips of identical function or different

functions, interconnected through buses. The plurality of chips may be also packaged as one chip. For example, the processor **151** may only comprise a central processing unit (CPU); or may comprise a combination of a CPU, a digital signal processor (DSP) and a chip of a communication controller, such as a chip of the communication unit **156**. The communication controller may comprise a controller of Ethernet, cellular, infrared, Bluetooth or wireless local area network (WLAN) communication devices. The CPU may comprise one or more computing cores. The communication controller may support direct memory access (DMA), and coordinate communication among components of the network communication device **100** or communication between the network communication device **100** and external devices.

Nonvolatile memory **153** stores an operating system and applications executable by the processor **151**. The processor **151** loads runtime processes and data from the nonvolatile memory **153** to a main memory **152**. The main memory **152** may comprise a random access memory (RAM), such as static RAM (SRAM) or dynamic RAM (DRAM). The non-volatile memory **153** may comprise an electrically erasable programmable read-only memory (EEPROM) or a flash memory, such as an NOR flash or an NAND flash.

FIG. 2 shows a network system for reducing a network addressing header. Network devices **100A** and **100B** are respectively two embodiments of the network communication device **100**. The network device **100A** maintains a database **165**, and the network device **100B** maintains a database **166**. The network device **100A** connects to an IPv6 network **206** through a port **102A**, and the network device **100B** connects to the IPv6 network **206** through a port **102B**.

The network device **100A** connects to a network gateway device **200A** in an IPv4 network **202A** through a port **101A**. The network gateway device **200A** is connected to a network terminal device **220A**. The network device **100B** connects to a network gateway device **200B** in an IPv4 network **202B** through a port **101B**. The network gateway device **200B** is connected to a network terminal device **220B**. The network device **100A** connects to an IPv6 network, such as the network **206**, through a port **102A**. The network device **100B** connects to an IPv6 network, such as the network **206**, through a port **102B**. Referring to FIGS. 1 and 2 together, the network communication device **100** connects to an IPv4 network, such as the network **202A** or **202B**, through the port **101**, and connects to an IPv6 network, such as the network **206**, through the port **102**. The ports **101A** and **101B** of the network devices **100A** and **100B** are examples of the port **101** of the network communication device **100**. The ports **102A** and **102B** of the network devices **100A** and **100B** are examples of the port **102** of the network communication device **100**.

With reference to FIG. 3, the network communication device **100** executes a method for reducing a network addressing header to transfer network packets. The network device **100A** of FIG. 2 is given as an example of the network communication device **100** in the following description. The processor **151** of the network communication device **100** executes the steps in the following order.

The processor **151** receives a first packet **300** in a communication originating from a source device and addressed to a recipient device, and determines whether a 4over6 function is enabled (step S2). The communication may comprise a session, such as a session carrying VoIP packets, media streaming packets, or others. The source device may comprise the network communication device **100** or another device connected with the network communication device **100**. In the example of the network device **100A** in FIG. 2, the processor

**151** receives the first packet **300** through the port **101A**. The first packet **300** may for example be transmitted along a communication path from either the network gateway device **200A** or the network terminal device **220A** to either the network gateway device **200B** or the network terminal device **220B**, and in each case the communication path is via both the network devices **100A** and **100B**. Thus, the communication transferring the first packet **300** is carried out across a first network of a first addressing scheme of IPv4 and a second network of a second addressing scheme of IPv6.

The 4over6 function is a function of establishing a channel in an IPv6 network to allow IPv4 packets to pass. If the 4over6 function is not enabled, the process of the method is terminated. If the 4over6 function is enabled, step S3 is executed. The processor **151** in step S3 processes payloads and addressing headers of the packets. For example, as a voice over Internet protocol (VoIP) gateway connected with a telephone, the network communication device **100** in step S3 converts audio signals from the telephone to generate real-time transport protocol (RTP) packets as the payloads, and generates IPv4 addressing headers of the RTP packets.

As shown in FIG. 4, if the first packet **300** comprises a payload **301**, and an IPv4 addressing header **310** representing a first IPv4 address, the processor **151** retrieves the first packet **300** and utilizes a converter **160** to convert the first IPv4 address into a mapping index **320** before transmitting the first packet **300** to the IPv6 network **206** (step S8). The converter **160** may comprise a machine-readable program which performs the conversion. The converter **160** may be stored in the main memory **152** or the nonvolatile memory **153**. The first IPv4 address comprises a source IPv4 address **311** and a destination IPv4 address **312**, as shown in FIG. 4. For example, the mapping index **320** is a 32-bit binary number. Embodiments of the converter **160** comprise a hash function that converts the first IPv4 address of the first packet **300** into the mapping index **320**. Although the mapping index **320** is generated from the IPv4 header **310** of the first packet **300**, the converter **160** in an alternative embodiment may generate the mapping index **320** from a user datagram protocol (UDP) header.

With reference to FIG. 5, the processor **151** generates a least significant segment in a second IPv6 address from the mapping index **320**. For example, the processor **151** utilizes the mapping index **320** as a least significant segment in a second IPv6 address. The processor **151** encapsulates the first packet **300** with an IPv6 addressing header **330**. The IPv6 header **330** comprises a source IPv6 address **331** and a destination IPv6 address **332**. An IPv6 address comprises a global routing prefix, a subnet identification, and an interface identification. Accordingly, the source IPv6 address **331** comprises a global routing prefix **3311**, a subnet identification **3312**, and an interface identification **3313**; and the destination IPv6 address **332** comprises a global routing prefix **3321**, a subnet identification **3322**, and an interface identification **3323**. The interface identification **3313** is a least significant segment of the source IPv6 address **331**, and the interface identification **3323** is a least significant segment of the destination IPv6 address **332**. The mapping index **320** may constitute either or both of the interface identification **3313** and the interface identification **3323**.

Packet routing in an IPv6 addressing scheme utilizes higher significant bits in an IPv6 address prior to a least significant segment in an IPv6 address. The higher significant bits constitute a more significant segment in the IPv6 address, and lower significant bits constitute the least significant segment in the IPv6 address. Therefore, the mapping index **320**

5

may be inserted into the interface identification **3313** or **3323** without affecting routing of the first packet **300** in the IPv6 network **206**.

After generating the mapping index **320**, the processor **151** determines whether or not the database **165** records an index identical to the mapping index **320** (step **S10**). If the determination is “no,” that is, no index identical to the mapping index **320** exists in the database **165**, the first packet **300** is a first transmitted packet in the communication between the source IPv4 address **311** and the destination IPv4 address **312**, and the processor **151** stores in the database **165** a record **410** of the mapping index **320** for the first packet **300**. The communication may comprise a session, such as a session carrying VoIP packets, media streaming packets, or others. Additionally, the processor **151** generates the IPv6 header **330** of the first packet **300** utilizing the mapping index **320** and retains the IPv4 header **310** of the first packet **300**, so that a network communication device, such as the network device **100B**, receiving the first packet **300**, maintains a correlation, such as a relationship **420**, between an address in the IPv4 header **310** and the mapping index **320** (step **S14**).

If an index identical to the mapping index **320** exists in the database **165**, the first packet **300** is not the first transmitted packet in the communication between the source IPv4 address **311** and the destination IPv4 address **312**, and the processor **151** need not store a redundant record **410** of the mapping index **320** for the first packet **300** in the database **165**. The communication may comprise a session, such as a session carrying VoIP packets, media streaming packets, or others. Additionally, the processor **151** generates the IPv6 header **330** of the first packet **300** from the mapping index **320** and removes the IPv4 header **310** of the first packet **300**, so that a network communication device, such as the network device **100B**, receiving the first packet **300**, may utilize the mapping index **320** to retrieve the address in the IPv4 header **310** according to the correlation, such as the relationship **420**, between an address in the IPv4 header **310** and the mapping index **320**, and recover the IPv4 header **310** of the first packet **300** (step **S12**).

In steps **S12** and **S14**, the IPv6 header **330** is generated as shown in FIGS. **4** and **5**, such that the least significant bits of an address in the IPv6 header **330** comprise a primary key to retrieve the first IPv4 address in the IPv4 header **310** from the database **165** and the database **166**.

The processor **151** transmits the first packet **300** to the IPv6 network **206** through the port **102**. In the embodiment, the processor **151** of the network device **100A** transmits the first packet **300** to the IPv6 network **206** through the port **102A** (step **S16**).

With reference to FIG. **6**, when receiving network packets, the network communication device **100** executes a header recovery process for reducing a network addressing header. The network device **100B** is given as an example of the network communication device **100** in the following description. The processor **151** of the network communication device **100** executes the steps in the following order.

When receiving the first packet **300**, the network device **100B** retrieves a mapping index, such as the mapping index **320**, in the IPv6 header **330** of the first packet **300** (step **S20**). Then the network device **100B** determines whether or not retrieval of such mapping index **320** is successful (step **S22**).

In the example of FIG. **2**, if the mapping index **320** in the IPv6 header **330** is not successfully retrieved, the network device **100B** determines if the first packet **300** comprises the IPv4 header **310** (step **S30**). If the first packet **300** comprises the IPv4 header **310**, the network device **100B** routes the first packet **300** according to the IPv4 header **310**, and transmits

6

the first packet **300** through the port **101B** to a target device in the IPv4 network **202B** (step **S36**). If the first packet **300** does not comprise the IPv4 header **310**, the network device **100B** reports an error utilizing Internet control message protocol (ICMP) packets (step **S32**).

If the mapping index **320** in the IPv6 header **330** is successfully retrieved, the network device **100B** determines whether or not the database **166** records an index identical to the mapping index **320** (step **S24**). If no such index identical to the mapping index **320** exists in the database **166**, the first packet **300** comprises a first transmitted packet in the communication between the source IPv4 address **311** and the destination IPv4 address **312**, and the network device **100B** stores in the database **166** a record of the mapping index **320** for the first packet **300**. The communication may comprise a session, such as a session carrying VoIP packets, media streaming packets, or others. Additionally, the network device **100B** determines whether or not the IPv4 header **310** of the first packet **300** is successfully retrieved (step **S26**). If the first packet **300** does not comprise the IPv4 header **310**, the network device **100B** reports an error utilizing Internet control message protocol (ICMP) packets (step **S32**). If the IPv4 header **310** of the first packet **300** is successfully retrieved, the network device **100B** establishes a correlation, such as the relationship **420**, between an address in the IPv4 header **310** and the mapping index **320** (step **S28**). Then the network device **100B** routes the first packet **300** according to the IPv4 header **310**, and transmits the first packet **300** through the port **101B** to a target device in the IPv4 network **202B** (step **S36**).

Additionally, the network device **100B** generates the IPv6 header **330** of the first packet **300** utilizing the mapping index **320** and retains the IPv4 header **310** of the first packet **300**, so that a network device, such as the network device **100A**, receiving the first packet **300** establishes a correlation, such as the relationship **420**, between an address in the IPv4 header **310** and the mapping index **320** (see step **S14**).

If an index identical to the mapping index **320** exists in the database **166**, the first packet **300** is not the first transmitted packet in the communication between the source IPv4 address **311** and the destination IPv4 address **312**, and the network device **100B** need not store a redundant record of the mapping index **320** for the first packet **300** in the database **166**. Accordingly, the processor **151** retrieves the IPv4 address of the first packet **300**, which is the source IPv4 address **311** and the destination IPv4 address **312**, from the database **166** according to the mapping index **320** (step **S34**). Then the processor **151** recovers the IPv4 header **310** of the first packet **300** utilizing the IPv4 address (step **S38**). Then the network device **100B** routes the first packet **300** according to the IPv4 header **310**, and transmits the first packet **300** through the port **101B** to a target device in the IPv4 network **202B** (step **S36**). After that, the IPv4 network device **202B** routes the first packet **300** according to the IPv4 header **310**.

Although utilized as an example in FIG. **6**, the IPv4 header **310** and IPv4 address of the first packet **300** may be replaced by a user data protocol (UDP) header of the first packet **300**.

With reference to FIG. **7**, if a second packet **300B** with a payload **301B**, a source IPv4 address **312** and a destination IPv4 address **311** is received, the network device **100B** may utilize the method in FIG. **3** to process the second packet **300B** and input an IPv4 addressing header **310B** to the converter **160** to generate a mapping index **320B** of the second packet **300B** as an interface identifier of an IPv6 addressing header **330B** of the second packet **300B**. The network device **100B** may utilize the method in FIG. **3** to process the second packet **300B** and generate a modified second packet **300C**

7

from the second packet **300B**. Compared to the first packet **300**, the IPv4 addresses **312** and **311** have been interchanged in the second packet **300B**, such that the mapping index **320B** generated by the converter **160** is different from the mapping index **320**. The network device **100A** can not utilize the mapping index **320B** to retrieve the IPv4 address of the first packet **300** and the second packet **300B**. Thus, the network device **100A** can generate a counter index **320A** along with the mapping index **320**.

With reference to FIG. 4, the network device **100A** performs a swap operation **161** on the IPv4 address in the IPv4 header **310** of the first packet **300** to generate an inverted address **310A**. The swap operation **161** may comprise a machine-readable program which performs the swap. The arrangement of a source address and a destination address in the IPv4 header **310** of the first packet **300** is interchanged through the swap operation **161** to be utilized as the inverted address **310A**. The program for the swap operation **161** may be stored in the main memory **152** or the nonvolatile memory **153**.

The network device **100A** inputs the inverted address **310A** to the converter **160** to generate the counter index **320A**. To the extent that the inverted address **310A** is identical to the IPv4 header **310B**, the counter index **320A** is identical to the mapping index **320B**.

With reference to FIG. 8, when receiving the modified second packet **300C** comprising the mapping index **320B** identical to the counter index **320A**, the network device **100A** retrieves a record **430** from the database **165** based on the counter index **320A** in the IPv6 header **330**, and utilizes the record **430** to recover the inverted address **310A**. The inverted address **310A** constitutes an IPv4 addressing header **310D** of the modified second packet **300C**. In other words, the network device **100A** utilizes the IPv4 header **310D** having the inverted address **310A** to encapsulate the modified second packet **300C** and thus generate a further modified second packet **300D**. The network device **100A** removes the IPv6 header **330B** from the further modified second packet **300D**, and then transmits the further modified second packet **300D** through the port **101A** to the IPv4 network **202A**.

In conclusion, packet routing in an IPv6 addressing scheme utilizes higher significant bits in a higher priority than the least significant segment in an IPv6 address. The higher significant bits constitute a more significant segment in the IPv6 address. Therefore, the mapping index may be inserted into the interface identification without affecting packet routing in an IPv6 network. The least significant bits of an address in an IPv6 header comprise a primary key to retrieve an IPv4 address in an IPv4 header from a database. The least significant bits of an address in the IPv6 header are thus utilized to recover an IPv4 header of a packet, such that the IPv4 header may be optionally disregarded or removed.

The foregoing disclosure of various embodiments has been presented for purposes of illustration. It is not intended to be exhaustive or to be limited to the precise forms described. Many variations and modifications of the embodiments described herein will be apparent to one of ordinary skill in the art in light of the disclosure. The scope of the disclosure is at least commensurate with the claims appended hereto and their equivalents.

What is claimed is:

1. A method for reducing a network addressing header which is executed in a network communication device, the method comprising:

retrieving a first packet for communication between a source device and a destination device across both a first communication network of a first addressing scheme

8

and a second communication network of a second addressing scheme, wherein the first addressing scheme and second addressing scheme are different;

retrieving and converting a first address of the first packet into a mapping index under a condition that the first packet is encapsulated with a first header representing the first address conforming to the first addressing scheme;

generating a least significant segment of a second address conforming to the second addressing scheme based on the mapping index for encapsulation of the first packet with a second header representing the second address, and wherein packet routing according to the second addressing scheme utilizes a more significant segment of the second address in a higher priority than the least significant segment, and the least significant segment comprises a primary key for retrieval of the first address; transmitting the first packet;

applying a swap operation on the first address to generate an inverted address conforming to the first addressing scheme, wherein an arrangement of a source address and a destination address in the first address is interchanged to form the inverted address;

generating a counter index based on the inverted address; recovering the inverted address based on the counter index upon reception of a first subsequent packet comprising the counter index, wherein the counter index comprises a least significant segment of a fourth address conforming to the second addressing scheme represented by a third header of the first subsequent packet, and the inverted address comprises a third address conforming to the first addressing scheme;

encapsulating the first subsequent packet with a fourth header representing the inverted address;

removing the third header from the first subsequent packet; and transmitting the first subsequent packet.

2. The method of claim 1, wherein the first addressing scheme comprises one of Internet protocol version 4 and user datagram protocol (UDP), and the second addressing scheme comprises Internet protocol version 6, and the method further comprises:

removing the encapsulation of the first header from the first packet.

3. The method of claim 2, wherein the least significant segment comprises least significant bits in an interface identification field in an address field of the second header.

4. The method of claim 1, wherein the first subsequent packet is received from the first port of the network communication device connected to an Internet protocol version 6 (IPv6) network.

5. The method of claim 1, further comprising:

transmitting the first subsequent packet through a second port of the network communication device connected to an Internet protocol version 4 (IPv4) network.

6. The method of claim 1, wherein the first packet is transmitted through a first port of the network communication device operable to connect to an Internet protocol version 6 (IPv6) network.

7. A network communication device comprising:

a communication unit for retrieving a first packet for communication between a source device and a destination device across both a first network of a first addressing scheme and a second network of a second addressing scheme, wherein the first addressing scheme and second addressing scheme are different; and

a processor connected to the communication unit and for executing a method for reducing a network addressing header, the method comprising:

retrieving and converting a first address of the first packet into a mapping index under a condition that the first packet is encapsulated with a first header representing the first address conforming to the first addressing scheme;

generating a least significant segment of a second address conforming to the second addressing scheme based on the mapping index for encapsulation of the first packet with a second header representing the second address, wherein packet routing according to the second addressing scheme utilizes a more significant segment of the second address other than the least significant segment, and the least significant segment comprises a primary key for retrieval of the first address;

transmitting the first packet;

applying a swap operation on the first address to generate an inverted address conforming to the first addressing scheme, wherein an arrangement of a source address and a destination address in the first address is exchanged to form the inverted address;

generating a counter index based on the inverted address;

recovering the inverted address based on the counter index upon reception of a first subsequent packet comprising the counter index, wherein the counter index comprises a least significant segment of a fourth address conforming to the second addressing scheme represented by a third header of the first subsequent packet, and the inverted address comprises a third address conforming to the first addressing scheme;

encapsulating the first subsequent packet with a fourth header representing the inverted address;

removing the third header from the first subsequent packet; and

transmitting the first subsequent packet.

8. The network communication device of claim 7, wherein the first addressing scheme comprises one of Internet protocol version 4 and user datagram protocol (UDP), the second addressing scheme comprises Internet protocol version 6, and the method further comprises:

removing the encapsulation of the first header from the first packet.

9. The network communication device of claim 8, wherein the least significant segment comprises least significant bits in an interface identification field in an address field of the second header.

10. The network communication device of claim 7, wherein the first subsequent packet is received from the first port of the network communication device connected to an Internet protocol version 6 (IPv6) network.

11. The network communication device of claim 7, wherein the method further comprises:

transmitting the first subsequent packet through a second port of the network communication device connected to an Internet protocol version 4 (IPv4) network.

12. The network communication device of claim 7, wherein the first packet is transmitted through a first port of the network communication device operable to connect to an Internet protocol version 6 (IPv6) network.

13. A network communication system comprising:

a first network communication device for retrieving a first packet for communication between a source device and a destination device across both a first network of a first addressing scheme and a second network of a second addressing scheme, wherein the first addressing scheme

and second addressing scheme are different, and for executing a method for reducing a network addressing header, the method comprising:

retrieving and converting a first address of the first packet into a mapping index under a condition that the first packet is encapsulated with a first header representing the first address conforming to the first addressing scheme;

generating a least significant segment of a second address conforming to the second addressing scheme based on the mapping index for encapsulation of the first packet with a second header representing the second address, wherein packet routing according to the second addressing scheme utilizes a more significant segment of the second address other than the least significant segment, and the least significant segment comprises a primary key for retrieval of the first address;

transmitting the first packet;

applying a swap operation on the first address to generate an inverted address conforming to the first addressing scheme, arrangement of a source address and a destination address in the first address is exchanged to form the inverted address, and the inverted address comprises a third address conforming to the first addressing scheme;

generating a counter index based on the inverted address;

recovering the inverted address based on the counter index upon reception of a first subsequent packet comprising the counter index, wherein the counter index comprises a least significant segment of a fourth address conforming to the second addressing scheme represented by a third header of the first subsequent packet;

encapsulating the first subsequent packet with a fourth header representing the inverted address;

removing the third header from the first subsequent packet; and

transmitting the first subsequent packet.

14. The network communication system of claim 13, wherein the first addressing scheme comprises one of Internet protocol version 4 and user datagram protocol (UDP), and the second addressing scheme comprises Internet protocol version 6, and the method further comprises:

removing the encapsulation of the first header from the first packet.

15. The network communication system of claim 14, wherein the least significant segment comprises least significant bits in an interface identification field in address field of the second header.

16. The network communication system of claim 13, further comprising:

a second communication device for executing an addressing header recovery method, wherein the addressing header recovery method further comprises:

utilizing the least significant segment in the second address as the primary key to store an association relationship between the first address and the least significant segment in a database.

17. The network communication system of claim 16, wherein the addressing header recovery method further comprises:

utilizing the least significant segment in the second address as the primary key to locate the first address in a database if the first header has been removed from the first packet; and

recovering the first header of the first packet utilizing the first address.

18. The network communication system of claim 13, wherein the method further comprises:

11

transmitting the first subsequent packet through a port of the network communication system connected to an Internet protocol version 4 network.

19. A method for reducing a network addressing header which is executed in a network communication device, the method comprising:

retrieving a first packet for communication between a source device and a destination device across both a first communication network of a first addressing scheme and a second communication network of a second addressing scheme, wherein the first addressing scheme and second addressing scheme are different;

retrieving a first address of the first packet under a condition that the first packet is encapsulated with a first header representing the first address conforming to the first addressing scheme;

applying a swap operation on the first address to generate an inverted address conforming to the first addressing

12

scheme, wherein an arrangement of a source address and a destination address in the first address is interchanged to form the inverted address;

generating a counter index based on the inverted address; recovering the inverted address based on the counter index upon reception of a first subsequent packet comprising the counter index, wherein the counter index comprises a least significant segment of a fourth address conforming to the second addressing scheme represented by a third header of the first subsequent packet, and the inverted address comprises a third address conforming to the first addressing scheme;

encapsulating the first subsequent packet with a fourth header representing the inverted address;

removing the third header from the first subsequent packet; and

transmitting the first subsequent packet.
